

Rice Straw Phytolith to enhance CO₂ capture: Ideas for sustainable management of rice straw and reduction of greenhouse gases from paddy soils

Pham Vu, Phong

Nguyen, Ngoc

Silicate weathering processes have immobilized CO₂, contributing to the regulation of greenhouse gas effects. Due to the similarity between composition of silicate and phytolith (an amorphous silica defined as Si precipitated in plant), it is hypothesized that phytolith is also able to sequester CO₂ in form of HCO₃⁻/CO₃²⁻. In this work, rice straw phytolith (RSP), a common residue from on-site burning of rice straw after harvesting, was examined in terms of CO₂ capture via batch adsorption experiments with a CO₂ aeration system. Captured amount of CO₂ was calculated by monitoring CO₂ release from aeration system which was adsorbed in NaOH solution with phenolphthalein as an indicator. pH, solution chemistry, and surface charge of RSP were monitored to provide relevant data on the interaction between CO₂ and phytolith. A comparison in discolorations of NaOH solutions was utilized to assess RSP's ability to capture CO₂. Presence of RSP resulted in a pH increase from 7.0 to 9.9 while in CO₂ aeration, the pH increased from 5.2 to 5.7. This suggested for a release of alkaline metals accompanying with dissolution of phytolith structure, which motivated CO₂ sequestration. The presence of CO₂ decreased phytolith dissolution from 31.9 to 18.8 mgSi /L and increased surface charge from -1001 to -605 mV, suggesting that H⁺ or alkaline ions neutralized phytolith surface charge, whereas the concentration of H⁺ might sequester more CO₂. It is suggested that as an enhancer of CO₂ capture, RSP may reduce CO₂ emission in paddy areas and contribute to the sustainable management of rice straw. The role of phytolith in reducing CO₂ on a global scale should be investigated and will be included in our further studies.
