

A Novel Treatment for *Candida glabrata* Infection

Filler, Elan

Candida glabrata is a fungus that causes life threatening infection in humans. Recently, some strains have become resistant to current antifungal drugs such as caspofungin, and new drugs are urgently needed. Last year, I discovered that the transcriptional regulator Ada2 is required for *C. glabrata* to resist antimicrobial peptides and caspofungin, and is necessary for virulence in *Galleria mellonella* (wax moth) larvae. My hypothesis is that a compound that inhibits Ada2 can potentially be used to treat *C. glabrata* infection. My objective was to discover a new drug to treat *C. glabrata* infection. Computer-assisted modelling, docking, and screening were used to identify potential Ada2 inhibitors. Ten of these compounds were selected based on structural diversity and availability and were purchased from a commercial source. To test for toxicity, each compound was injected into *G. mellonella*, and survival was monitored over a seven day period. Each non-toxic compound was tested for its capacity to protect *G. mellonella* from lethal *C. glabrata* infection using survival as the endpoint. Computer modelling generated a list of 400 potential Ada2 inhibitors. Of the 10 compounds that were selected and tested, only three were non-toxic. Of these three, the compound 6-methyl-2-oxo-N-(2-pyridylmethyl)-1H-pyridine-3-carboxamide significantly improved survival of infected *G. mellonella* in two separate experiments ($p=0.011$ as compared to control by the log-rank test). Therefore, the compound 6-methyl-2-oxo-N-(2-pyridylmethyl)-1H-pyridine-3-carboxamide is a promising antifungal drug for treating *C. glabrata* infection.
