

Palm Leaf Waste-to-Hydrogen Conversion via Modified Graphene Oxide-Supported Ni–Co Electrocatalyst

Awadh, Mawaddah (School: University Schools)

The transition to a clean energy is limited by the high cost of green hydrogen production, relying on expensive noble metals electrocatalysts. This creates supply chain risks and restricts large-scale deployment. Also, large amounts of unused palm leaf waste posing an environmental challenge. Solving these two issues, this work aims to convert palm leaf carbon source to a cost-effective and sustainable graphene oxide (GO) nanosheets loaded with Ni/Co as an electrocatalyst for hydrogen production via electrochemical water splitting. GO were synthesized from palm through pyrolysis and hydrothermal oxidation, then used as a conductive support for Ni/Co nanocomposites prepared at different ratios (2:1, 1:1, 1:2). The catalysts were evaluated for hydrogen evolution reaction (HER) in acidic (0.5 M H₂SO₄) and in alkaline (1 M KOH) media. Structural and morphological analyses (SEM, TEM, XRD, and FTIR) confirmed uniform dispersion of Ni/Co on GO. Electrochemical testing revealed that Ni/Co (1:1)-GO electrode exhibited superior performance with lowest overpotential, and charge transfer resistance. Quantifying the output, ~1.5L of H₂ was produced over 24h using small cell with 90% activity, demonstrating high stability. Enhanced performance is explained by synergistic Ni/Co-GO interactions, increasing active sites and accelerates electron transfer. With 1:1 optimal ratio, Ni is best at splitting water, and Co facilitates optimal hydrogen adsorption for hydrogen binding, that accelerates the overall hydrogen evolution kinetics. The work demonstrates a scalable waste-to-material strategy for efficient, low-cost H₂ production, advancing sustainable energy technologies.
